Topical Hypothermia is More Efficient Than Ischemic Preconditioning in Ameliorating Hepatic Ischemia Reperfusion Injury in Rat Liver Through Hypoxia Inducible Factor Independent Mechanisms

Physiology Department, Faculty of Medicine, Ain Shams University, Cairo, Egypt.

Abstract

Background: Hepatic ischemia reperfusion (IR) injury is common with many medical strategies as liver transplantation and trauma. Aim: is comparing the efficacy and evaluating the possible mechanisms of ischemic preconditioning (IPC) and topical hypothermia (TH) in the hepatic IR injury. Method: 56 adult male albino rats were allocated into four groups: sham control group (n=15), hepatic ischemia reperfusion group (IR) (n=13): where ischemia compromised 70% of the liver for 45 min followed by 90 min of reperfusion, topical hypothermia (TH-IR) group (n=14): liver temperature was maintained during ischemia at 10°C, ischemic preconditioning group (IPC-IR) (n=14): 10 minutes of ischemia followed by 10 minutes of reperfusion prior to hepatic ischemia reperfusion. ALT, AST and ALP were measured in serum while malondialdehyde (MDA), glutathione peroxidase (GPX), hypoxia inducible 1 alpha (HIF1α), tumor necrosis factor alpha (TNFα), cytochrome c (Cyt c), adenosine triphosphate (ATP) and dynamin related protein (DRP1) were measured in hepatic tissue in addition to the histological examination. Results: TH and IPC significantly reduced AST, MDA, TNFα, Cyt c and DRP1 expression. TH preserved hepatic integrity, normalized both AST and ALT, increased hepatic GPX and reduced MDA while IPC did not increase GPX and has less significantly reduced MDA compared to hypothermia. ATP was significantly higher with hypothermia compared to IPC. Hypothermia decreased significantly the level of HIF1α while preconditioning increased its level. Conclusion: Hypothermia was more protective against IR injury compared to IPC despite reduced metabolic reprogramming signal HIF1α. Hypothermia effect was through improvement of REDOX state and mitochondrial bioenergetics.

Keywords
- Ischemia reperfusion injury
- Hepatic hypothermia
- Hepatic ischemic preconditioning
- Hypoxia inducible factor1 α (HIF1α)
- ATP

INTRODUCTION

Ischemic reperfusion (IR) injury is common with many medical strategies such as percutaneous coronary intervention and coronary artery bypass grafting (1), effective thrombolysis therapy of stroke (2) and might be considered the transplant surgeon’s enemy during kidney transplantation (3).

The liver is subjected to two types of IR injury, the first type takes place during liver surgery, trauma and hemorrhagic shock and called warm IR injury while the second form occurs during the hypothermic preservation and storage of the organ for transplantation and called cold IR injury (4). Vascular occlusion techniques are used for avoiding excessive blood loss during liver surgery (5). Thus, a better understanding of hepatic IR injury may lead to improvements of the clinical care of many patients, particularly those undergoing surgery with extended ischemia.

The mechanisms of hepatic IR injury are attributed to multiple factors such as oxidative stress and ROS generation through multiple pathways (6, 7). For instance, it reduces ATP availability resulting in Ca$^{++}$ channels failure and its accumulation inside the cells with a subsequent activation of intracellular enzymes such as phospholipase C, protein kinase C which induces hepatic necrosis and apoptosis. IR injury also disturbs mitochondrial function due transition of mitochondrial membrane permeability and mitochondrial swelling (8). Additionally, it increases also transcription of inflammatory chemokines and cytokines such as TNFα, IL1β, IL6, and IL12 (17), to have potent anti-apoptosis activity (18), to decrease the effect of IR on mitochondrial activity and to increase the energetic bio-availability (19). These effects of hypothermic perfusion lead to a scientific thinking to use hypothermia as a preconditioning model in isolated perfused rat liver (20,21) and to provide a promising strategy to prepare the liver against ischemic damage (22).

On the other hand, little is known about clinical application of hypothermia in human. Hypothermia was reported to represent a double-edged sword: if hypothermic preservation can help against the damaging effects of ischemia, a prolonged hypothermia can be accompanied by worse recovery which was observed with renal recovery during kidney transplantation and was suggested to lead to mitochondrial dysfunction and pro-apoptotic signal transduction (23). Hypothermia with its advantages has been reported also to have undesirable side effects, including cell swelling, acidosis, altered enzyme activity, calcium accumulation, and production of ROS (24).
Ischemic preconditioning (IPC) means transient brief episodes of sublethal ischemia preceding a subsequent prolonged ischemia, which has been found to enhance organ resistance to ischemic injury (ischemic tolerance) as manifested in diverse organs and tissues including the heart, brain, liver and kidney (25). Additionally, IPC was reported to suppress mitochondrial depolarization, improved ATP production and inhibited the generation of reactive oxygen species (ROS) (26). However, the exact mechanism by which IPC confers protection against hepatic IR injury has not been completely elucidated (27). Few studies have reported that IPC does not prevent hepatic IR injury (28) while other studies were advised to confirm the benefit of IPC during hepatic IR injury (27).

In this study the efficacy of both IPC and topical hypothermia preconditioning to ameliorate hepatic IR injury are going to be evaluated. In addition, the study tries to probe if there are any differences in the mechanisms by which they interact with the hepatic tissue. Therefore, the changes in liver cell integrity as deduced by histological examination and biochemical assays of hepatic and mitochondrial functions in addition to evaluation of the REDOX state are going to be studied as possible interactive mechanisms.

Material and Methods:

Experimental Animals:
The study was performed on 56 male albino adult rats, weighing 180-250 grams at the start of the study. Rats were maintained in the Medical Ain Shams Research Institute (MASRI) under standard conditions of boarding throughout the whole period of the study.

Animals were housed in animal cages (4 rats / cage) with suitable ventilation, temperature of 22-25°C; 12 hours light dark cycle and free access to food and water ad-libitum in the animal house. Animals were not exposed to unnecessary pain or stress. Animal manipulation was performed with maximal care and hygiene.

All rats received care in accordance with the national health guidelines and the research ethical committee of Faculty of Medicine Ain Shams University. Further the Ain Shams Faculty of Medicine Ethical Committee approval was obtained.

Experimental protocol:

Starting number of rats in each group was 15 with total 60 rats for the four groups and the final number is 56 rats due to death rate of 2 rat in IR group, of 1 rat in TH group and 1 rats in IPC group.

Rats were randomly allocated into 4 groups:
1- Sham control group (n=15)
2- Hepatic ischemia reperfusion group (IR) (n=13)
3- Topical hypothermia (TH-IR) group (n=14)
4- Ischemic preconditioning group (IPC-IR) (n=14)

Experimental procedures:

Ischemia reperfusion: On the day of sacrifice, rats were weighed and injected intraperitoneally by sodium thiopental in a dose of 40 mg/kg body weight (29). After a midline laparotomy, all structures in the portal triad (hepatic artery, portal vein, and bile duct) to the left lobe and median liver lobes were occluded with atraumatic microvascular clamp for 45 minutes. The occlusion spared to the branches of the right and
caudate lobe resulting in 70% liver ischemia (30). Reperfusion was done by the end of 45 minutes ischemia by removal of the clamp for 90 minutes (31). The wound was closed temporarily by 2-0 silk sutures during reperfusion. This method of partial hepatic ischemia prevented mesenteric venous congestion by permitting portal decompression through the right and caudate lobes (32).

**Induction of topical hypothermia:** In the hypothermia group a plate made of polystyrene was placed over the rat body to isolate the left lateral and median liver lobes from other body parts in order to avoid induction of systemic hypothermia. After induction of ischemia the isolated lobes were surrounded by packs filled with ice. Ice packs were replaced every 10-15 min with new ones. A surface probe (Digital Thermometer (ranging from -50°C to 300°C, China ) was placed between median and lateral left lobes to measure the liver core temperature that was maintained at 10°C (33). Rats body were covered by warm blankets and body temperature was continuously monitored rectally with the rectal digital Thermometer (Rosamax, Switzerland) to keep body temperature between 36°C and 37°C that was monitored (33).

**Ischemic preconditioning:** In the Ischemic preconditioning group, Ischemic preconditioning was produced by 10 minutes of ischemia followed by 10 minutes of reperfusion prior to the 45 minutes of ischemia which is followed by 90 minutes of reperfusion (34).

In the sham group, all structures in the portal triad were exposed but were not subjected to ischemia.

**Sample collection:** At the end of reperfusion period, the abdominal aorta was exposed and blood was collected into serum tubes which were stored at -80 until subjected to the biochemical assays. Median lobe of the liver was stored at -80°C until subjected to the biochemical assays. Parts of the left lobe of the liver were preserved in10% formalin for H&E examination of the hepatic tissue. 8 samples of hepatic tissue were taken for measurement of HIF1α and TNFα and 6 hepatic tissue samples were taken for measurement of Cyt c, ATP and DRP1.

**Biochemical analysis:**

**Determination of serum level of ALT, AST and ALP:**

**Serum liver enzymatic activity:** Alanine amino transferase (ALT), Aspartate aminotransferase (AST) were measured colorimetrically according to manufacturer’s protocol using commercial kits supplied by Bio-diagnostic (Egypt).

**Serum alkaline phosphatase (ALP):** was measured colorimetrically according to manufacturer’s protocol using commercial kits supplied by Bio-diagnostic (Egypt).

**Determination of hepatic tissue level of MDA and glutathione peroxidase (GPX) activity:**

Prior to tissue homogenization, the frozen hepatic tissue at -80°C, was allowed to thaw and was perfused with a PBS (phosphate buffered saline) solution, pH 7.4 containing 0.16 mg / ml heparin to remove any red blood cells and clots. The tissue sample was cut thoroughly, weighed and homogenized. The tissue was homogenized in 6 ml cold buffer (50 mM potassium phosphate, pH 7.5.) per gram tissue. Hepatic tissue homogenization was performed, using the
homogenizer: Karl Kolb, scientific technical supplies D−6072, Dreieich, West Germany. Samples were centrifuged at 4000 r.p.m for 15 minutes and the supernatant was removed for assay and stored at -80 to measure levels of MDA and GPX in hepatic tissue.

Hepatic tissue malondialdehyde (MDA): was measured by colorimetric method according to manufacturer’s protocol using kits supplied by Biodiagnostics, (Egypt). While Hepatic tissue glutathione peroxidase (GPX) activity was measured by UV method according to manufacturer’s protocol using kits supplied by Biodiagnostics, (Egypt).

**Determination of HIF1α, TNFα, Cyt c and ATP levels in hepatic tissue.**

8 tissue samples were taken for measurement of HIF1α and TNFα. Also 6 tissue samples were taken for the measurements of cyt c, ATP and DRP1.

Hepatic tissue homogenization was performed in the homogenization buffer (pH: 7.2) by adding 9 mL buffer for each 1 gm tissue. The homogenization HEPES buffer (Sigma) consisted of: (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) (HEPES), ethylene-diamine-tetraacetic acid (EDTA), Dithiothreitol (DTT), phenylmethylsulfonyl fluoride (PMSF). After homogenization, samples were centrifuged for 5 min. at 5000 r.p.m. The supernatant was separated and used for determination of HIF1α, TNFα, ATP and Cyt c levels in hepatic tissue. For ATP measurement hepatic tissue was homogenized (10 mg) in 100 ml ATP assay buffer.

**Hepatic tissue hypoxia-inducible factor 1alpha (HIF1α):** was estimated by enzyme-linked immunosorbent assay (ELISA) according to manufacturer’s protocol using kits supplied by (Fine Test, China).

**Hepatic tissue tumor necrosis factor alpha (TNFα):** were estimated by ELISA according to manufacturer’s protocol using kits supplied by (Fine Test, China).

**Hepatic tissue cytochrome c (Cyt c):** Assays of liver tissue levels of Cyt c was carried out by ELISA, according to manufacturer’s protocol, using kits for rat supplied by (Elabscience, USA).

**Hepatic tissue ATP level:** was measured colorimetrically, according to manufacturer’s protocol using commercial kits supplied byBiovision (USA).

**Determination of Hepatic tissue Dynamine related protein (DRP1):**

It was measured by using polymerase chain reaction (PCR), at first total RNA extraction was performed using Qiagen tissue extraction kit (Qiagen, USA) according to instructions of manufacture. The total RNA (0.5–2 μg) was used for cDNA conversion using high capacity cDNA reverse transcription kit Fermentas, USA). Quantitative PCR used SYBR Green I Master mix and analysis were performed using an Applied Biosystem with software version 3.1 (StepOne™, USA). The qPCR assay with the primer sets were optimized at the annealing temperature. DRP1 expression were normalized to the β-actin. The primer sequence for DRP1 was (Forward primer: 5′- GGAATCTTCTTCTTCTTCTGAC -3′, Reverse primer: 5′- CCAGTGCAGGGTCCGAGGT -3′), while the primer sequence of beta actin was (Forward primer 5′-TGTGAGACCTTTCAACACC-3′, and Reverse primer 5′-CGCTCATTGCCGATAGTGTGAT-3′). The relative quantitation was calculated according to Applied
Bio system software using specific applied equations.

**Histological examination of liver tissue:**

Left lobes of liver were fixed in 10% neutral-buffered formalin solution. The specimens were dehydrated in ascending grades of alcohol, cleared in xylene and embedded in paraffin wax. Serial sections, 5 um thick were cut and stained with Hematoxylin and Eosin. The stained sections were examined by using the light microscope for evaluation of histological changes (35).

**Statistical analysis**

Data were expressed as means ±SEM. ANOVA was used to find significance between means of multiple groups. This is followed by LSD (least significant difference) to find intergroup statistical significance with $p \leq 0.05$ considered significant. For correlation studies, person correlation coefficient was calculated by linear regression analysis using the Least Square Method and correlation of $p \leq 0.05$ was considered statistically significant.

All statistical data were analyzed using SPSS program (Statistical Package for Social Science) version 20 (36).

**Results:**

Ischemia reperfusion injury resulted in significant increase in both ALT and AST compared to sham control group. Hypothermia resulted in significant decrease in both ALT and AST compared to IR group without significant difference to its corresponding values in control. Ischemic preconditioning resulted only in significant decrease in AST compared to IR but it is significantly higher than control. In addition, preconditioning showed no significant difference in ALT when compared to IR group. There was also no significant difference in ALP between all the studied groups (Table 1).

Regarding the oxidative stress biomarker, MDA level was significantly increased in IR group compared to sham group with significant decrease in GPX level compared to sham group. Hypothermia significantly decreased oxidative marker MDA and increased antioxidant enzyme GPX compared to IR group. IPC in this study decreased significantly the level of MDA compared to IR group but its level was significantly higher compared to its corresponding value in hypothermic group. IPC showed no significant change in level of GPX compared to IR group where its level was significantly less than sham control and significantly less than its corresponding values in hypothermic group (Table 2).

IR group showed significant increase in TNFα compared to control group. Rats in topical hypothermia and IPC groups showed significant decrease in TNFα compared to IR rats. However, topical hypothermia and IPC remained significantly higher in their TNFα level compared to sham control rats (Table 2).

IR significantly increased HIF1α compared to sham control group. Topical hypothermia showed significant decrease in HIF1α level compared to IR injury group, while IPC significantly increased HIF1α compared to IR injury and hypothermic groups (Figure 1).

ATP level significantly decreased in the IR group compared to sham group. Rats after topical hypothermia and IPC showed significant increase in ATP level compared to IR injury group. However, hypothermia manifested higher
ATP compared to preconditioning. Compared to control the level of ATP in both hypothermia and IPC groups remained significantly low (Figure 1).

Ischemia reperfusion showed significant increase in Cyt c and DRP1 level compared to sham control group. Both topical hypothermia and IPC resulted in significant decrease in both Cyt c and DRP1 level compared to IR injury group but the level remained significantly higher than control group (Figure 1).

As shown in Table (3) in the different studied groups except in control group, there is positive significant correlation between the level of serum AST and the hepatic tissue level of MDA, TNFα, Cyt c and DRP1. On the other hand a negative significant correlation was observed between the serum level of AST and hepatic GPX and ATP. Also there is a positive correlation between ALT and both of MDA and TNFα. In addition, there was a positive significant correlation between the level of MDA and the level of HIF1α as shown in (Figure 2)

Histological examination with H&E showed that liver tissue of control group have normal liver architecture formed of cords of hepatocytes hexagonal in shape radiating from central vein with blood sinusoids in-between them (Figure 3). Whereas, liver tissue of IR group stained with H&E showed massive distorted liver architecture and destructed hepatocytes in the form.
of degradation of its cytoplasmic content, ballooning of some cells and karyolysis of hepatic cell nuclei (Figure 3). On examination of liver tissue of hypothermia group showed minimal changes of liver tissue with intact hepatocytes and minimal hemorrhage in-between hepatic cells (Figure 3). On the other hand liver tissue of IPC group, livers showed vacuolation of most of hepatocytes and infiltration of polymorphic inflammatory cells with increased number of eosinophil (Figure 3).

Discussion:

Ischemia reperfusion (IR) injury is a clinically important issue in liver transplantation and in flow-controlled surgical operation. This study was aimed to compare between efficacy of ischemic preconditioning (IPC) and topical hypothermia in the protection from oxidant and cellular damage exerted by ischemia reperfusion in liver studying their interaction with cellular and mitochondrial level.

In this study both ALT and AST were significantly increased in IR group compared to sham group this result was in agreement with other studies (37,38). IR injury disturbs the hepatocellular membrane permeability causing hepatic enzymes leakage into the circulation (39). As ALT is more specific to cellular cytoplasm while AST is 20% specific to cellular cytoplasm and 80% to mitochondrial matrix (40), it could be concluded that IR injury affect both hepatocytes mitochondria and cytoplasm.

The non-significant changes in the liver enzyme alkaline phosphatase observed in this study among different studied groups could be due to the presence of hepatic ALP on the surface of bile duct epithelia and needs long time of cholestasis to increase (40,41).
Many studies were consistent to our findings of significantly increased hepatic tissue MDA (38), TNFα (42,43), cytochrome c (an indicator for disruption of mitochondrial integrity) (44), DRP1 (an indicator of increased fission and mitochondrial fragmentation) (45,46) and significant decrease of hepatic ATP levels (an indicator for defective mitochondrial generation of energy) (47) and GPX (48) in cases of IR injury. The previous findings confirm the lesion on cellular and mitochondrial level. The positive significant correlation between the level of AST on one hand with MDA, TNFα, Cyt c and DRP1 on the other hand, and its negative correlation with ATP level demonstrated respectively the role of oxidative stress, inflammation, disturbed mitochondrial integrity, dynamics and energetics in pathophysiology of IR injury. It is of interest to see a positive significant correlation between ALT level and both MDA and TNFα without significant correlation with the mitochondrial parameters (ATP, Cyt c and DRP1) supporting that AST is more related to mitochondria involvement.

**Common effects to both hypothermia and preconditioning:**

In the current study, both ischemic preconditioning and topical hypothermia exhibited their ability to decrease significantly the level of liver enzyme AST, MDA, TNFα, Cyt c and DRP1 compared to IR group.

These changes are supported by other studies with IPC which showed drastic reduction of AST 6 hours after reperfusion (34), significant decrease in TNFα and MDA (49), decreased Cyt c protein expression with both condition of ischemic pre and post conditioning in rats with lightening of apoptosis (50). Although there is a little about changes in DRP1 and in IPC, yet, the increased phagosomes appeared in the histological picture in this study may be supportive to its increase. Recently, in vitro IPC increased mitophagosome formation, enhanced the delivery of mitophagosomes to lysosomes and promoted the clearance of damaged mitochondria in kidney (26). Regarding the conflicting reports about the effects of IPC on hepatic IR injury, although few studies have reported that IPC does not prevent hepatic IR injury (28), we, at least partially, are in agreement with those reported certain beneficial effects and found that IPC can limit the deleterious effects of hepatic IR injury (51).

On the other hand, the previously mentioned effects are supported by other studies with hypothermia which showed significantly reduced AST and ALT using freezing solution dripped on the surface of ischemic lobes (52) reduced IR-induced lipid peroxidation and oxidative stress with mild hypothermia (53). Despite there are no enough knowledge about the relationship between hypothermia, Cyt c and DRP1 in hepatic IR injury, their low levels in this study could be considered indicators for better mitochondrial integrity in hypothermic livers. These results may be supported by an earlier study (54) which found that reducing metabolic demand through hypothermia increased survival and reduced the vulnerability of cortical mitochondria during severe hypoxemia in kidney. Also the inverse correlation between the measured ATP level and Cyt c in hypothermic group in this study (r= -0.813, p<0.04, n=6) confirmed how the availability of ATP decreased the release of Cyt c hypothermia has been showed
to provide neuroprotective against global cerebral IR injury, which is, at least partially, ascribed to the inhibition of DRP1 and Cyt c expression and the protection of mitochondrial structure (55,56). Also hypothermia reported to promote mitochondrial elongation in cardiomyocytes through reduction of DRP1 fission activity together with an associated decrease in cellular O₂ consumption (57).

The effects in which hypothermia is more efficient compared to preconditioning:

Compared to IPC group, hypothermia was more efficient in preservation of integrity of hepatic structure as evidenced by the histological section as well as the significant decrease of both AST and ALT to a level that is not differ significantly from sham control. Whereas IPC showed only ameliorating effect on AST level which even remained significantly higher than control. In this work, the non- significant change in serum ALT in IPC group is consistent to an early study (27). On the other hand, hypothermia was showed to preserve hepatic tissue, prolong cell viability and reduce oxidative stress parameters (58).

Also hypothermia increased the level of hepatic antioxidant GPX concomitant with the reduction of MDA while preconditioning was unable to increase GPX and its effect in reducing MDA was significantly less than that of hypothermia (17). Therefore, topical hypothermia was more effective than IPC in protection of liver against oxidative stress, precluding the need to activate second-line antioxidant defenses to further protects against IPC. In addition, hypothermia was able to increase ATP level significantly more than that of IPC which is an indicator for better mitochondrial function and bioenergetics.

Compared to IR group, hypothermia decreased significantly the level of hypoxia inducible factor (HIF1α) while preconditioning increased its level.

Indeed HIF1α in this study is significantly increased with IR compared to sham control which is consistent with others who reported increased expression of HIF1α and HIF2α in many liver diseases including IR-induced liver injury (59). Metabolic reprogramming under hypoxia was one of the first functions ascribed to HIF1α activity. HIF1α is continuously synthesized in the cytosol and is rapidly degraded by the 26S proteasome under normoxic conditions in contrast to proteolytically stable beta subunit. When oxygen is limiting, HIFα became stabilized and then translocated to the nucleus where it binds to specific gene named hypoxia response elements (HREs). Thereafter, accumulated HIFα dimerise with HIFβ subunits and recruit additional transcriptional co-activators to transactivate the transcription of hypoxia-responsive genes (60).

HIF1α signaling is considered to support anaerobic ATP production by up-regulating glycolytic enzymes (61,62) and down-regulating oxidative phosphorylation enzymes thus reducing the cell’s reliance on oxygen-dependent energy production (63). Also HIF1 signaling is important for HIF-mediated suppression of ROS. HIF signaling also up-regulates the expression of SOD, a mitochondrial enzyme capable of converting the superoxide free radical to H₂O₂ which can then be converted to harmless water and oxygen by catalase enzymes. HIF mediates also regulation of mitochondrial mass and mediate
adaptive responses to tissue hypoxia (60).

The enhanced expression of HIF1α with ischemic preconditioning in this study is described before in hepatocytes (64) where HIF1α activation was reported to be associated with the induction of a long lasting tolerance to hypoxic injury (65) and to promote cell survival during IR liver injury (66,67). However, despite its increased expression with IPC as manifested in this study, it did not provide valuable protection against IR injury.

Also the reduced expression of HIF1α with hypothermia may be attributed to ability of hypothermia to improve REDOX state compared to IR and IPC (decreased MDA and increased GPX) since stabilization HIFα in the start of hypoxia is attributed to ROS (68). Herein, the positive significant correlation between MDA and level if HIF is supportive to this concept. Also the ability of hypothermia to reduce the inflammatory insult on hepatocyte manifested by the reduced TNFα level may explain its role in inhibiting HIF1α expression since inflammation and its mediators are HIF activators (69).

In addition, the effect of hypothermia in reducing Cyt c may be an additive role. It has been showed before that nitric oxide produced by cytochrome c oxidase helps in stabilization of HIF1α in hypoxic mammalian cells (70).

Conclusion:

Hypothermia showed more efficacy compared to IPC in protection against hepatic IR injury. The effect of hypothermia in reducing this metabolic reprogramming signal (HIF1α) did not prevent its overwhelming effect in protection against IR injury compared to IPC. So, the protection, therefore, appears to be HIF1α independent and may be accomplished through other interactive mechanisms. Hypothermia induced its effect through improvement of REDOX state and mitochondrial bioenergetics.
