Abstract: Liver fibrosis is considered as a progressive pathological process involving multiple cellular and molecular events that lead to deposition of excess matrix proteins in the extracellular space. When that process is combined with ineffective regeneration and repair, there is increasing distortion of the normal liver architecture, and the end result is cirrhosis. Emerging anti-fibrotic therapies are aimed at inhibiting the accumulation of fibrogenic cells and/or preventing the deposition of extracellular matrix proteins. Although many therapeutic interventions are effective in experimental models of liver fibrosis, the mechanisms underlying the anti-fibrotic effect on liver fibrosis remain unclear. The aim of the present study was to investigate the underlying mechanisms of anti-fibrotic effect of angiotensin converting enzyme inhibitor (ACEI) on experimental liver fibrosis induced by carbon tetrachloride (CCl4). Thirty five white albino male rats of 150-200g average weight were randomly divided into three groups, Group I: The control group (n = 10), Group II: CCl4 injected rats without any treatment (n = 10) and Group III: CCl4 injected rats that received an ACEI, perinodopril, dissolved in distilled water, 6mg/kg/day for 4 weeks (n = 15). Venous blood was collected from retro orbital vein for serum separation for assessment of liver functions. Liver tissue was subdivided into three portions for: pathological examination, estimation of transforming growth factor-β1 (TGF-β1) and matrix metalloproteinase-9 (MMP-9) by ELISA and expression of nuclear factor- kappa beta (NF-κB) in a trial to understand the mechanism underlying the anti-fibrotic effect of ACEI. Tissue TGF-β1, MMP-9 and NF-κB were significantly higher in CCl4 group (group II) compared with control group (group I) and they were decreased significantly with administration of ACEI with CCl4 (group III). In conclusion, ACEI attenuates the progression of hepatic fibrosis induced by CCl4 by reducing expression of NF-κB, TGF-β1, and MMP-9.

Key words: liver fibrosis, TGF-β1, MMP-9 and NF-κB

Introduction:

Chronic liver injury is caused by a variety of insults, including viral hepatitis, alcohol, drug abuse and autoimmune hepatitis. It is associated with increased inflammatory cell infiltration and may involve the interplay of different inflammatory mediators, which is a common stage in most of chronic liver diseases. If treated properly in that stage, hepatic fibrosis can be reversed and its progression to irreversible cirrhosis, which leads to lethal complications and high mortality, may be prevented. Currently, there is no established therapy to delay or reverse the progression of liver fibrosis (1). Once cirrhosis develops, liver transplantation is the only therapy to avoid a fatal condition (2). Therefore, an accurate assessment of liver fibrosis is very important in order to predict the prognosis and start the appropriate prophylactic therapy to prevent disease progression. Liver biopsy (LB) is still the gold-standard method for assessing liver fibrosis (3, 4, 5). However, it is difficult to perform LB for all patients who need to be assessed repeatedly due to its invasiveness and prohibitive cost. In addition, biopsy samples are usually too small to diagnose the disease accurately and diagnostic opinions often differ among pathologists (6, 7). As a result, a pathological
examination does not always provide an accurate diagnosis. Recent studies work hard to assess a noninvasive method for the diagnosis and evaluation of the prognosis of liver fibrosis (8).

Recently, several lines of evidence have suggested that the rennin-angiotensin system (RAS) plays an important role in the pathogenesis of organ fibrosis (9). Angiotensin II (Ang II) plays a central role in the regulation of systemic blood pressure and fluid homeostasis. Its action is mediated mainly by two subtypes of receptors, Ang II type 1 (AT₁) and Ang II type 2 (AT₂) receptors (10).

Moreover, the expression of TGF-β₁, the key cytokine in the development of organ fibrosis, is increased by Ang II and the blockade of the (RAS) by ACEI or by AT₁ antagonists has been shown to reduce the progression of organ fibrosis. However, the mechanisms underlying the anti-fibrotic effect of ACEI on liver fibrosis remain unclear (11).

It should be noted that, upon liver injury, hepatic stellate cells (HSCs) undergo morphological trans-differentiation to myofibroblast-like cells having a proliferative, fibrogenic and contractile phenotype; this process is known as activation. Activated HSCs express smooth muscle actin (SMA) and produce an excess of collagen and other ECM components (2).

In addition, activated HSCs secrete transforming growth factor-β₁ (TGF-β₁), which is a key mediator in human fibrogenesis leading to a fibrotic response and proliferation of connective tissue. Furthermore, HSCs disturb the balance between matrix metalloproteinases (MMPs) and the naturally occurring tissue inhibitors of metalloproteinases (TIMP 1 and 2), leading to matrix breakdown and replacement by connective tissue-secreted matrix (12).

Nuclear factor-κB (NF-κB) is a transcriptional factor, which binds to specific DNA motifs to regulate transcriptional activity of its target genes involved in HSCs activation (13) and releasing of pro-inflammatory cytokines such as tumor necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6), which are involved in the process of fibrogenesis (14).

Therefore, the aim of the present work is to further evaluate the anti-fibrotic effect of ACEI in rat liver fibrosis induced by CCl₄, and to study its relationship with the expression of NF-κB, TGF-β₁ and MMP-9.

Materials and methods:

Thirty five white albino male rats of 150-200g average weight were included in the study. They were bred in the animal house of Kasr Al-Aini Hospital, Cairo University. Rats were randomly divided into three groups:

Group I: (n = 10) control group, fed with regular rat chow.

Group II: (n = 10) fibrotic model, they received 0.2 ml CCl₄ subcutaneously twice weekly for 6 weeks.
Group III: (n = 15) model of liver fibrosis that received an ACE inhibitor, perinodopril, dissolved in distilled water, 6mg/kg/day for 4 weeks by oral feeding.

Sample collection and preparation: At the time of sacrifying the rats, venous blood was collected from retro orbital vein for serum separation for assessment of liver functions. Liver tissue was subdivided into three portions: The first portion was stored in formaldehyde for pathological examination. The second portion was stored at -70°C in lysis buffer that contains guanidinium thiocyanate and B-mercaptoethanol for RNA extraction. The third portion, also, was stored at -70°C in phosphate buffer saline for TGF-β₁ and MMP-9 assay by ELISA.

Liver functions:
Serum ALT and albumin were estimated by using conventional laboratory methods.

Measurement of TGF- β₁ and MMP-9:
About 19 mg of liver tissue was homogenized in one ml lysis buffer for protein extraction which contained 0.06 mol/l Tris buffer (pH 6.8), 2% SDS (sodium dodecyl sulphate), 100 mmol/l sodium fluoride and one mmol/l phenyl methyl sulfonyl fluoride (PMSF), supplied by sigma, St Louis, USA. After cell lysis, the homogenate was centrifuged at 10.000 rpm for 20 minutes at 4°C and the supernatant was examined for detection of TGF-β₁ and MMP-9 using the quantitative sandwich enzyme linked immuno-sorbent assay (ELISA). The kits were supplied by Ray Biotch, Inc.

Detection of NF-κB by RT-PCR:
RNA extraction:
Total RNA was extracted from liver tissue samples using the SV total RNA isolation system kit (Promega, Madison, USA) according to the manufacturer's recommendations.

RT-PCR:
cDNA was generated from 5mg of total RNA extracted with 20 pmol oligo dt primer and was denatured at 70°C for 2min. then a transcription mixture containing 50 mmol KCl, dNTPs and 200 units of MMLV reverse transcriptase were added, the reaction was placed at 42°C for one hour then at 95°C for 5 min. to stop the reaction. Then PCR reaction was performed by adding the PCR mix which contained 10mmol /l tris HCL pH 8.3, 2.3 units of taq polymerase, 100 mmol of NTPs and 100 mmol of each specific NF-κB primer with the following sequence, forward: CAGCCTCTTGGATAGCTGGG. Reverse:GTCAGGAGTTCGAGAACCAGC.

Then the reaction mixture was subjected to 40 cycles of 95°C for one min., 55°C for one min. and 72°C for 2min. after the last cycle a final extension at 72°C for 10 min was done.
Agarose gel electrophoresis:

All PCR products were electrophoresed on 2% agarose stained with ethidium bromide and visualized by UV Trans-illuminator. Fragment sizes were 113 pb.

Gel documentation:

The PCR products were semi-quantitated using the gel documentation system (BioDO, Analyser) supplied by Biometra.

Statistical analysis:

Numerical data was presented as mean ± SD. Differences between the three group parameters were compared by one way ANOVA. To study the relationship between the variables, Pearson's correlation coefficient was calculated. The results were considered statistically significant at P≤0.05.

Results:

Pathological assay:
Liver tissue samples from control rats (group I) showed normal lobular architecture with central veins and radiating hepatic cords (Figure 1A). Liver tissue samples from model group (group II) showed that more fibrous tissues were formed extending into the hepatic lobules to separate them completely. A large number of inflammatory cells infiltrated the intra-lobular and inter-lobular regions. The liver structure was disordered and there were more necrotic and fatty degenerated liver cells compared with the controls (Figure 1B). In the AC treated group (group III), hepatocyte degeneration, necrosis and infiltration of inflammatory cells were all apparently ameliorated and collagen deposition was, also, markedly reduced (Figure 1C).

![Figure 1](image)

Figure(1) Light microscopy showing normal liver tissue in control group (1A) (HE × 100), degenerated and necrotic liver cells associated with inflammatory cells in model group (1B) (HE × 40), attenuated necrosis and infiltration of inflammatory cells after ACEI treatment (1C) (HE × 40).

Liver function (table 1):

1- Serum albumin level is significantly lower in CCl4 group (group II) compared with control group (group I) (p< 0.05) and it increased significantly when treated with ACEI (group III).
2- Serum ALT increased significantly in CCl₄ group (group II) in comparison to control group (group I) (p< 0.05) and it decreased significantly when treated with ACEI (group III).

**NF-κB expression:**

Tissue NF-κB increased significantly in CCl₄ group (group II) compared with control (group I) and it decreased significantly with administration of ACEI with CCl₄ (group III) (*Figures 4, 5*).
Discussion:

Liver fibrosis is characterized by the excessive accumulation of extracellular matrix proteins, including collagen, which occurs in most types of chronic liver diseases. The knowledge about the cellular and molecular mechanisms of liver fibrosis has been greatly advanced. Activated hepatic stellate cells, portal fibroblasts and myofibroblasts of bone marrow origin have been identified as major collagen-producing cells in the injured liver. These cells are activated by NF-κB and fibrogenic cytokines such as TGF-β1, TNF-α and IL-6 [13,15,16].

CCL₄-induced liver cirrhosis in rats exhibits several features of human liver diseases, including excessive fibrosis with uniform micronodular transformation, portal hypertension, ascites, and hyperdynamic circulation. Liver cirrhosis has been extensively investigated in terms of the biochemical and molecular mechanisms of its development and complications [17].
As regards liver function tests, the current study showed increased serum activity of ALT and decreased serum level of albumin in fibrotic model (group II), compared to controls (group I), indicating liver damage. But, after 6 weeks of treatment with perindopril, (group III), there was less liver damage indicated by lower ALT activity and higher albumin levels, suggesting that ACEI may attenuate CCl₄-induced liver fibrosis by down regulation of the inflammatory response in the liver (18).

Histological examination, also, demonstrated a significant correlation with the liver function assessment indicated by the infiltration of a large number of inflammatory cells in the intra-lobular and interlobular regions, formation of more fibrous tissue, also, the liver margin was uneven in the fibrotic model group (II) compared with the control group. In contrast, perindopril (group III) had obviously attenuated the extent of necrosis and reduced the immigration of inflammatory cells compared with the fibrotic model group.

In the present work, TGF-β₁ levels were increased significantly in the fibrotic model group (p<0.05) and were decreased significantly (p<0.05) after treatment with ACEI, but they did not return to the values of the control group.

ACEI (perindopril) could prevent hepatic fibrosis by down regulation of TGF-β₁ which leads to suppression of the activation of hepatic stellate cells (19). These results agreed with those of Powell et al. (20) who reported that the inheritance of polymorphisms in the TGF-β₁ and angiotensinogen genes and the influence of genotypes on the stage of hepatic fibrosis in patients with chronic hepatitis C. Patients who inherit neither of the pro-fibrogenic genotypes have no or only minimal fibrosis. The documentation raises the novel suggestion that Ang-II may be a mediator of fibrosis in the liver, and since a strong interaction between Ang II and TGF-β₁ has been clearly demonstrated, these results will open several ways for the use of ACEI in anti-fibrotic strategies in the future.

Matrix metalloproteinases (MMPs) are Zn-dependent endopeptidases. They are capable of degrading all kinds of extracellular matrix proteins, but, also, can process a number of bioactive molecules (21).

MMPs are initially synthesized as inactive zymogens with a pro-peptide domain that must be removed before the enzyme is active. The pro-peptide domain contains a conserved cysteine residue which interacts with the zinc in the active site and prevents binding and cleavage of the substrate keeping the enzyme in an inactive form. MMPs are activated by other MMPs, plasmin as well as other factors (22).

The activities of MMPs are inhibited by TIMPs (23). They are capable of inhibiting the activities of all known MMPs and play a key role in maintaining the balance between ECM deposition and degradation in different physiological processes, including liver fibrosis development (24).

In the present study, the level of MMP-9 was measured and was found to be increased significantly in the fibrotic model group (group II) (p<0.05) and decreased significantly (p<0.05) with administration of ACEI (group III). These data are in accordance with those of Senties et al. (25) who explained the suppressive effect of ACEI by its interaction with zinc at the active site of MMP-9 leading to its inactivation and thus relief fibrosis.
The associated increase in the levels of MMP-9 and TGF-β1 in fibrotic model group (group II) and the decrease in their levels after treatment with ACEI (group III) could explain the partial role of TGF-β1 in increasing the level of MMP-9 that lead to deposition of an excess of extra cellular matrix proteins in liver fibrosis (26).

Nuclear factor –Kappa Beta (NF-κB) is involved in the control of a large number of normal cellular processes such as inflammatory and immune responses, developmental processes, cell growth and apoptosis. Also, it is involved in several pathological conditions like arthritis, asthma, neuro-degenerative diseases, heart diseases, cancer and liver fibrosis (27). NF-κB, also, regulates expression and activation of matrix metalloproteinases (MMPs) (28).

In the current study NF-κB increased significantly in fibrotic model group (p <0.05) and decreased significantly in ACEI treated group (p<0.05) but did not reach the control group levels. These results are in agreement with those of Jonsson et al. (29), who reported that the dual effects of ACEI to inhibit the activity of NF-kB and MMP-2/9, in addition to reducing protein expression of TGF-β1, are likely to contribute to the anti-fibrotic actions of these agents.

Conclusion:

The present study demonstrated a significant relationship between angiotensin II and liver fibrosis. ACEI attenuates the progression of hepatic fibrosis induced by CCl4 by reducing expression of TGF-β1, NF-κB and MMP-9.

These results suggest that NF-κB, TGF-β1 and MMP-9 may be helpful as fibrosis markers but further studies are needed to discriminate accurately the stage of fibrosis as accurately as liver biopsy. This can limit the number of liver biopsies to patients whose clinical findings conflict with the biomarker results.

قسم الفيسيولوجيا، والكيمياء الحيوية الطبية

كلية الطب، جامعة القاهرة

يتضمن التهاب النسيج الليفي الكبد العديد من التغييرات الخلوية والجزئية التي تؤدي إلى إيداع الكثير من البروتينات في المنطقة خارج الخلايا. وعندما لا تصاحب هذه التغييرات عملية تجديد وإصلاح فعالة بسبب ذلك في النهاية إلى تليف الكبد. ويهدف علاج التهاب النسيج الليفي إلى تثبيط الخلايا السببية للتليف بالإضافة إلى منع إيداع البروتينات في المنطقة خارج الخلايا إلا أن الآليات التي يتم بها منع التليف لا تزال غير معروفة.

تهدف هذه الدراسة بحث الآليات التي يمنع بها مثبط الانزيم المحول للانجيوتينسين حدوث التليف. وقد اشتملت الدراسة على عدد 35 من الجرحان البيضاء من نوع الدم، تتراوح أوزانها بين 100-150 جرام وقد قسمت إلى ثلاث مجموعات:

* المجموعة الأولى الضابطة : تحتوى على عدد 10 جرذان.
* المجموعة الثانية : تحتوى على عدد 10 جرذان تم حقنها برابع كلوريد الكربون فقط.
* المجموعة الثالثة : تحتوي على عدد 15 من الجرحان تم حقنها برابع كلوريد الكربون والتي تم علاجها بمثبط الانزيم المحول للانجيوتينسين - بيريندوبيريل - (6 مل. / كجم / يوم لمدة 4 أسابيع) وقد تم جمع عينات الدم لتحلول وظائف الكبد، كما تم قياس عينات نسيج الكبد إلى ثلاثة أقسام للتحليل البالغولوجي للأنسجة والتعبير الجيني للعامل النووي كابا بيتا وقياس عامل النمو المحول بيتا - 1 وما تراكس ميتالوبروتينز - 9.

أوضح نتائج الدراسة أن هناك زيادة ذات دلالة إحصائية في التعبير الجيني للعامل النووي كابا بيتا وإيضاً في مستويات عامل النمو المحول بيتا وماتريكس ميتالوبروتينز - 9 في المجموعة الثانية مقارنة بالمجموعة الأولى الضابطة كما وجد نقصاً ذو دلالة إحصائية في هذه المتغيرات عند قياسهم في المجموعة الثالثة التي استخدم فيها المثبط كعلاج.

ونستخلص من هذه النتائج أن مثبط الانزيم المحول للانجيوتينسين يخفف من التهاب النسيج الليفي الكبد عن طريق تقليل التعبير الجيني للعامل النووي كابا بيتا ومستويات عامل النمو المحول بيتا - 1 وماتريكس ميتالوبروتينز - 9.
